(54) **Bus control apparatus.**

(57) A bus control apparatus is provided which can control the access timing between a central processing unit and a peripheral equipment without increasing the size and the cost of the entire system. The access timing between the central processing unit and the peripheral equipment is controlled in accordance with an operation timing of the peripheral equipment described in a timing table.

FIG. 2

This invention relates to a bus control apparatus suitable for use with, for example, a computer.

A conventional computer, may include a peripheral equipment such as, for example, an interface board which operates at a lower speed than the bus accessing speed of a CPU (central processing unit) of the computer. To resolve the mis-match of bus accessing speeds, the speed of the bus accessing by the CPU may be decreased in accordance with the bus accessing timing of the peripheral equipment; however, the processing speed of the entire apparatus is reduced as a result. Therefore, a so-called wait controller or a like apparatus may be provided in order to adjust the timing at which a read signal or a write signal developed from the CPU is to be supplied to the peripheral equipment.

Further, a conventional computer, may include peripheral equipment having a bus width different from that of the CPU, in particular, where, for example, the peripheral equipment uses a bus width of 8 bits while the CPU uses a bus width of 32 bits. In that case hardware apparatus for exclusive use for packing and unpacking data may be provided and data of 32 bits outputted from the CPU are divided (unpacked) into four groups of data of 8 bits to be supplied to the peripheral equipment whereas data of 8 bits outputted from the peripheral equipment are read-in in groups of four, to produce (pack) data of 32 bits to be supplied to the CPU.

By the way, such a wait controller as described above must be designed for each design of peripheral equipment to be connected to the computer. This makes the controller expensive.

Further, some peripheral equipment continue to output data for a while even after reading of data of the CPU from the peripheral equipment comes to an end, that is, have long floating times. Further, some other peripheral equipment are required to hold data on a data bus for a while even after outputting of a data write signal from the CPU to write data into the peripheral apparatus comes to an end, that is, have a long hold time.

With such peripheral equipment that has a long floating time or a long hold time, operation timings cannot be adjusted only by means of such a wait controller as described above and some special hardware contrivance is required for the peripheral equipment.

This has impact on the size and cost of the apparatus.

Further, the hardware apparatus for packing and unpacking data described above requires, similarly to a wait controller, individual designing of, for example, packing-unpacking trigger generation logic in accordance with the peripheral equipment to be connected to the computer, which again makes it expensive.

Furthermore, where peripheral equipment of a bus width of 8 bits is employed for a CPU of another

bus width of 32 bits as described above, when four data of 8 bits obtained by unpacking data of 32 bits outputted from the CPU are to be written into the peripheral equipment, if the peripheral equipment is, for example, a memory, the address into which data should be written must be incremented one by one four times, but if the peripheral equipment is an apparatus of the type which has a buffer of a so-called FIFO (first-in first-out) type and for which reading and writing of data are performed at a fixed address, the peripheral equipment must be constructed so that the four data of 8 bits are written into the same fixed address.

In the present specification, whether, when data are written into or read out from the peripheral equipment having a bus width different from that of a CPU, the address is incremented or fixed as described above is referred to as addressing type.

The hardware apparatus described above, however, is not constructed such that the address of a peripheral equipment into or from which data are to be written or read out is designated taking the addressing type of the peripheral equipment into consideration.

Accordingly, for example, an application program must be designed and programmed taking the addressing type of the peripheral equipment into consideration, which is cumbersome.

It is an object of the present invention to provide a bus control apparatus which can control communications of data between a CPU and the peripheral equipment without increasing the size and the cost of the entire system.

According to the present invention, there is provided a bus control apparatus for interconnecting a plurality of bus lines, comprising:

a main bus to which a central processing unit is connected;

a sub bus to which a peripheral equipment is connected;

storage means for storing an operation timing of said peripheral equipment; and

control means for controlling an access timing between said central processing unit and said peripheral equipment in accordance with the operation timing of said peripheral equipment stored in said storage means.

The invention also provides a bus control apparatus for interconnecting a plurality of bus lines, comprising:

a main bus to which a central processing unit is connected;

a sub bus to which a peripheral equipment is connected;

storage means for storing a bus width and an addressing type of said peripheral equipment;

data latch means for latching data outputted from said central processing unit or said peripheral

equipment;

address latch means for latching an address outputted from said central processing unit to said peripheral equipment; and

control means for controlling packing/unpacking of data latched in said data latch means in accordance with the bus width of said peripheral equipment stored in said storage means and controlling the address latched in said address latch means in accordance with the addressing type of said peripheral equipment stored in said storage means.

In the bus control apparatus, the access timing between the central processing unit and the peripheral equipment is controlled by the control means in accordance with the operation timing of the peripheral equipment stored in the storage means. Accordingly, a special hardware apparatus such as, for example, a wait controller for adjusting the accessing timing between the central processing unit and the peripheral equipment need not be provided for each item of peripheral equipment which may be connected to the main bus or the sub bus. Consequently, the access timing between the central processing unit and the peripheral equipment can be controlled without increasing the size and the cost of the entire system.

Preferably, the operation timing of the peripheral equipment stored in the storage means is re-writable so that, even if the specifications of the peripheral equipment are modified or new peripheral equipment is added, it is unlikely that it will not be possible to use the apparatus.

The storage means may store at least a hold time or a recovery time of the peripheral equipment. In this instance, the timing can be controlled in accordance with the hold time or the recovery time.

Preferably, the main bus has a bus width greater than the bus width of the sub bus, and more preferably, the bus width of the main bus is equal to an integral number of times the bus width of the sub bus.

In the version of the bus control apparatus equipped with the data latch means, data outputted from the central processing unit or the peripheral equipment are latched by the data latch means, and an address outputted from the central processing unit to the peripheral equipment is latched by the address latch means. Packing/unpacking of the data latched in the data latch means is controlled in accordance with the bus width of the peripheral equipment stored in the storage means while the address latched in the address latch means is controlled in accordance with the addressing type of the peripheral equipment stored in the storage means. Accordingly, an application program can be designed without taking packing/unpacking of data and the addressing type into consideration, and consequently, an application program of high universality in use can be provided.

Preferably, the bus width and the addressing type of the peripheral equipment stored in the storage

means are re-writable so that, even if the specifications of the peripheral equipment are modified or a new peripheral equipment is added, it is unlikely that it will be impossible to use the apparatus.

The invention will be further described by way of non-limitative example with reference to the accompanying drawings, in which:-

FIG. 1 is a block diagram showing a computer to which a bus control apparatus of the present invention is applied;

FIG. 2 is a detailed block diagram of a gateway of the computer shown in FIG. 1;

FIG. 3 is a timing table illustrating operation of the computer shown in FIG. 1;

FIG. 4 is a bus width table showing bus widths and addressing types employed in the computer shown in FIG. 1;

FIG. 5 is a time chart illustrating operation of the computer shown in FIG. 1 when data are read out from a first device to a CPU;

FIG. 6 is a similar view but illustrating operation of the computer shown in FIG. 1 when data are written from the CPU to a second device;

FIG. 7 is a similar view but illustrating operation of the computer shown in FIG. 1 when data are read out from a ROM to the CPU;

FIG. 8 is a similar view but illustrating operation of the computer shown in FIG. 1 when data are written from the CPU to the first device; and

FIGS. 9 to 14 are flow charts illustrating operation of the gateway shown in FIG. 2.

Referring first to FIG. 1, there is shown a computer which includes a gateway to which a bus control apparatus of the present invention is applied. The computer shown include a CPU 1 which may be, for example, a 32-bit CPU and executes predetermined processes in accordance with a system program stored in a ROM (read only memory) 5 and/or an application program stored in a RAM (random access memory) 2. The RAM 2 is, for example, a high speed DRAM (dynamic RAM) of a 32-bit width and temporarily stores an application program or data necessary for operation of the system. A device 3 is, for example, a high speed device of a 32-bit width and performs predetermined processing such as sound processing or image processing.

The CPU 1, the RAM 2 and the device 3 are connected to a main bus 9 in the form of a 32-bit high speed bus, and data of 32 bits are communicated at a high speed between the CPU 1 and the RAM 2 or the device 3 by way of the main bus 9.

The ROM 5 is, for example, a ROM of an 8-bit width and stores a system program stored in advance therein. A backup memory 6 is, for example, a memory of a 16-bit width and stores data as backup data. A device 7 is, for example, a device of an 8-bit width and executes predetermined processing such as sound processing or image processing. Another de-

vice 8 is, for example, an input/output interface of a 16-bit width.

The ROM 5, the memory 6 and the devices 7 and 8 operate at a operation speed lower than that of the CPU 1 and are connected to a sub bus 10 as a general purpose bus of, for example, 16 bits. It is to be noted, however, that the ROM 5 and the device 7 of an 8-bit width are connected to the lower 8 bits of the sub bus 10 of 16 bits.

It is to be noted that, though not shown, the main bus 9 and the sub bus 10 are each constituted from a data bus, an address bus and a control bus.

A gateway 4 is connected between the main bus 9 and the sub bus 10 and controls communications of data between the CPU 1 and the ROM 5, the memory 6 or the device 7 or 8.

Referring now to FIG. 2, the gateway 4 includes, for example, a data buffer 11, four multiplexers (MUX) 12a to 12d, a timing table storage section 13, a bus width storage section 14, a counter 15, a controller 16, a main address decoder 17, an address table storage section 18, a sub bus address decoder 19, a status buffer 20, and an address buffer 21.

It is to be noted that each broken line in FIG. 2 denotes a control signal line.

The data buffer 11 is controlled by the controller 16 such that it latches data of 32 bits supplied thereto from the CPU 1 by way of the main bus 9 and outputs four data of 8 bits from the uppermost bit of the 32-bit data to the multiplexers 12a to 12d, respectively. Meanwhile, the data buffer 11 latches data from the multiplexers 12a to 12d of 8 bits and outputs them as 32-bit data to the main bus 9.

The multiplexers 12a to 12d constructed with an 8-bit width are controlled by the controller 16 such that they latch four data of 8 bits from the data buffer 11 and output them as two data of 16 bits or four data of 8 bits to the 10. Meanwhile, the multiplexers 12a to 12d latch two data of 16 bits or four data of 8 bits from the sub bus 10 and outputs them as data of 32 bits to the data buffer 11.

The timing table storage section 13 stores in advance therein such a timing table as shown in FIG. 3 in which, for example, read delay times, write delay times, hold times, floating times and recovery times of the ROM 5, the memory 6 and the devices 7 and 8 connected to the sub bus 10 are described.

It is to be noted that the read delay time or the write delay time signifies the access time when data are read or written, and the hold time signifies the time for which data must be held on a bus after outputting of a write signal comes to an end. Further, the floating time signifies the time for which data must be held on a bus even after reading of data comes to an end, and the recovery time signifies the time interval necessary when a same peripheral equipment is to be connected and accessed (the interval of time which must be provided before a next access after a first ac-

cess comes to an end).

The bus width table storage section 14 stores in advance such a bus width table as illustrated in FIG. 4 in which the data lengths (hereinafter referred to as bus widths) handled by the ROM 5, the memory 6, and the devices 7 and 8 connected to the sub bus 10 and the addressing types of them are described.

It is to be noted that, in the bus width table of FIG. 4, any peripheral equipment whose addressing type is fixed (in the present embodiment, the devices 7 and 8) has a data buffer of, for example, the FIFO type and requires designation of a predetermined same address (fixed address) upon reading or writing of data divided into a plurality of sets by unpacking. On the other hand, any other peripheral equipment whose addressing type is variable (in the present embodiment, the ROM 5 and the memory 6) requires, upon reading or writing of data divided into a plurality of sets by unpacking, incrementing or decrementing of the address to designate a new address for reading or writing of data of a next data set after reading or writing of data of one of the data sets.

The counter 15 counts a system clock (System Clock) supplied thereto from a clock generator not shown by way of the main bus 9 and the controller 16.

The controller 16 varies the timing of a read (Read) signal or a write (Write) signal supplied thereto from the CPU 1 by way of the main bus 9 in accordance with the timing table (FIG. 3) stored in the timing table storage section 13 and outputs a resulted signal as an SRead signal or an SWrite signal to the sub bus 10. Further, the controller 16 outputs a DataOK signal, which will be hereinafter described, at a predetermined timing in accordance with the timing table (FIG. 3) stored in the timing table storage section 13.

Furthermore, the controller 16 controls the data buffer 11 in accordance with a bus width described in the bus width table (FIG. 4) stored in the bus width table storage section 14 and an AccessType (length of data handled by the CPU 1) supplied thereto from the CPU 1 by way of the main bus 9 to pack or unpack data. Meanwhile, the controller 16 controls the address buffer 21 in accordance with an addressing type described in the bus width table (FIG. 4) stored in the bus width table storage section 14.

The main bus address decoder 17 decodes an address (Address) outputted from the CPU 1 by way of the main bus 9 and compares a result of such decoding with an address decode table stored in the address table storage section 18. The main bus address decoder 17 then determines from a result of the comparison whether the peripheral equipment the CPU 1 tries to access is the RAM 2 or the device 3 connected to the main bus 9, and if it determines that the peripheral equipment is the RAM 2 or the device 3, it outputs a chip select signal to the RAM 2 or the device 3 by way of the main bus 9.

The address table storage section 18 stores in advance the address decode table in which results of decoding of addresses allocated to the RAM 2, the device 3, the ROM 5, the memory 6 and the devices 7 and 8 are described.

The sub bus address decoder 19 decodes an address outputted from the CPU 1 by way of the main bus 9 and the address buffer 21 and compares a result of such decoding with the results of decoding of the addresses described in the address decode table of the address table storage section 18 and allocated to the RAM 2, the device 3, the ROM 5, the memory 6, and the devices 7 and 8. The sub bus address decoder 19 then determines from a result of the comparison whether or not the peripheral equipment the CPU 1 tries to access is the ROM 5, the memory 6, or the device 7 or 8 connected to the sub bus 10, and outputs, when it determines that the peripheral equipment is one of the peripheral equipment connected to the sub bus 10 (that is, one of the ROM 5, the memory 6, and the devices 7 and 8), a chip select signal to the peripheral equipment by way of the sub bus 10.

The status buffer 20 stores the peripheral equipment to which one of the main bus address decoder 17 and the sub bus address decoder 19 has outputted a chip select signal last, that is, that one of the peripheral equipment which has been accessed last by the CPU 1 (a result of decoding of the address allocated to the peripheral apparatus). Further, when the stored value of the status buffer 20 is the same as that one of the peripheral equipment to which the sub bus address decoder 19 has outputted the chip select signal, that is, when accessing to an arbitrary one of the peripheral equipment connected to the sub bus 10 has occurred successively, the status buffer 20 outputs a control signal to the controller 16 to execute recovery processing which will be hereinafter described.

The address buffer 21 latches an address supplied thereto from the CPU 1 by way of the main bus 9. The address buffer 21 then holds the thus latched address as it is or increments (or decrements) the latched address by one at a predetermined timing.

Subsequently, operation of the computer will be described. In order to facilitate description, control of the timings and control of the bus width and the addressing type which are actually performed simultaneously will be described separately from each other below.

First, control of the timings will be described with reference to the flow charts of FIGS. 5 and 6. It is to be noted that, in FIGS. 5 and 6, the signals Read, DataOk, ChipSelect, SRead, and SWrite are indicated in the active-low logic. Further, it is assumed that each block of the system operates in synchronism with the timing of a rising edge of a system clock ((a) in FIG. 5 and (a) in FIG. 6).

When, for example, the CPU 1 tries to read out

data of one byte (8 bits) from the device 7, the address (Address) ((c) of FIG. 5) allocated to the device 7 is outputted from the CPU 1 by way of the main bus 9 so that it is latched by the address buffer 21 and inputted to the main bus address decoder 17.

The address latched by the address buffer 21 is outputted as a signal SAddress ((h) of FIG. 5) to the sub bus 10 and outputted also to the sub bus address decoder 19.

The main bus address decoder 17 and the sub bus address decoder 19 decode the address received from the CPU 1, and results of the decoding are compared with the address decode table stored in the address table storage section 18.

Since the address allocated to the device 7 is held outputted from the CPU 1 as described above, it is detected by the sub bus address decoder 19 that the peripheral equipment the CPU 1 tries to access is the device 7, and a chip select signal (ChipSelect) ((f) of FIG. 5) is outputted from the CPU 1 to the device 7 by way of the sub bus 10.

The result of decoding of the sub bus address decoder 19 is stored into the status buffer 20 and then outputted from the status buffer 20 to the controller 16. Consequently, it is recognized by the controller 16 that the object for accessing of the CPU 1 is the device 7.

Further, a read signal (Read) ((b) of FIG. 5) and an accessing type signal (AccessType) indicative of byte accessing are supplied from the CPU 1 to the controller 16 by way of the main bus 9.

When the controller 16 receives the read signal (Read) from the CPU 1, it outputs a read signal (SRead) ((g) of FIG. 5) to the sub bus 10.

Here, the device 7 has a read delay time of 2 clocks as seen from the timing table of FIG. 3. In particular, a time for two clocks is required before the device 7 outputs data to the sub bus 10 after a chip select signal and a read signal (SRead) are supplied thereto.

Thus, after the controller 16 outputs the read signal (SRead) to the sub bus 10, it resets the counter 15 and causes the counter 15 to start counting beginning with 0 at the timing of a system clock ((a) of FIG. 5).

Further, the controller 16 refers to the read delay time of the device 7 described in the timing table (FIG. 3) of the timing table storage section 13 and places a waiting time until the count value of the counter 15 becomes equal to the read delay time of the device 7.

Accordingly, in this instance, the waiting time of 2 clocks is placed after the read signal (SRead) is outputted.

After the time for two clocks elapses after the read signal (SRead) is outputted to the sub bus 10, one-byte data (SData) ((i) of FIG. 5) are outputted from the device 7 to the lower 8 bits of the sub bus 10 of 16 bits, and a control signal based on the 8-bit

(one-byte) signal AccessType representative of an accessing type from the CPU 1 is outputted from the controller 16 to the multiplexer 12d and the data buffer 11 so that data of the lower 8 bits of the sub bus 10 may be latched.

Consequently, the one-byte data (SData) from the device 7 are latched at the lower 8 bits of the data buffer 11 by way of the multiplexer 12d.

After the data (SData) from the device 7 are latched by the data buffer 11, a DataOk signal ((e) of FIG. 5) indicating that it is enabled to output data from the device 7 to the main bus 9 is supplied from the controller 16 to the CPU 1 by way of the main bus 9, and the read signal (SRead) ((g) of FIG. 5) which has been outputted from the controller 16 to the sub bus 10 is stopped.

Further, in this instance, the controller 16 resets the counter 15 so that the counter 15 starts counting beginning with 0 at the timing of a system clock ((a) of FIG. 5).

Then, the data latched by the data buffer 11 are outputted to the main bus 9 ((d) of FIG. 5) so that they are read in by the CPU 1.

The CPU 1 then stops outputting of the read signal (Read) ((b) of FIG. 5) and the address (Address) ((c) of FIG. 5) to the main bus 9. After the CPU 1 stops outputting of the read signal (Read) ((b) of FIG. 5) to the main bus 9, the controller 16 causes the sub bus address decoder 19 to stop outputting of the chip select signal (ChipSelect) ((f) of FIG. 5) to the device 7.

Thereafter, the controller 16 causes, after the floating time of the device 7 elapses after the time at which the data from the device 7 are latched by the data buffer 11 (reading of the data comes to an end) and outputting of the data (SData) ((i) of FIG. 5) from the device 7 to the sub bus 10 is stopped, that is, the count value of the counter 15 becomes equal to the floating time of the device 7 described in the timing table (FIG. 3), the address buffer 21 to stop outputting of the address (SAddress) ((h) of FIG. 5) to the sub bus 10.

By the way, the CPU 1 recognizes, at the point of time when outputting of the address (Address) ((c) of FIG. 5) to the main bus 9 is stopped as described above, that accessing to the device 7 has been completed (actually such accessing has been completed with the CPU 1).

Accordingly, if the case wherein, for example, it is tried to write data into the memory 6 connected to the sub bus 10 immediately after the CPU 1 stops outputting of the address (Address) ((c) of FIG. 5) to the main bus 9 is considered, then for a time until the floating time (2 clocks) of the device 7 elapses after the point of time when data from the device 7 are latched by the data buffer 11 (reading of data comes to an end), that is, for a time until the point of time indicated at P₁ in FIG. 5 is passed, the device 7 continues to output the data (SData) to the sub bus 10, and

accordingly, the data come across on the sub bus 10 with data outputted from the CPU 1 to the memory 6.

Therefore, the gateway 4 is constructed so that, in this instance, the data outputted from the CPU 1 are latched by the data buffer 11 and a signal DataOk indicating that writing of data into the memory 6 has been completed is outputted from the controller 16 to the CPU 1.

Consequently, the CPU 1 recognizes that writing of data into the memory 6 has been completed (although such writing has not been completed as yet). Accordingly, the main bus 9 is released immediately, and the CPU 1 can thereafter execute any processing except the process of accessing to any of the peripheral equipment connected to the sub bus 10.

Meanwhile, in the gateway 4, after it is waited that the floating time of the device 7 elapses after the point of time when data from the device 7 are latched by the data buffer 11 (reading of data comes to an end) (it is waited that the point P₁ of time (FIG. 5) comes), a write signal (SWrite), a chip select signal or an address (SAddress) is outputted from the controller 16, the sub bus address decoder 19 or the address buffer 21 to the memory 6 by way of the sub bus 10. Then, the data from the CPU 1 latched by the data buffer 11 are outputted to and written into the memory 6 by way of the sub bus 10.

Accordingly, in this instance, the CPU 1 can execute writing processing of data into the memory without waiting the lapse of the floating time of the device 7 after the point of time at which data from the device 7 are latched by the data buffer 11 (reading of data comes to an end). Consequently, the processing speed of the entire apparatus can be enhanced.

Further, in this instance, writing processing of data into the memory 6 is transferred from the CPU 1 to the gateway 4 and accordingly is thereafter executed by the gateway 4. Accordingly, the CPU 1 can immediately execute any other processing. Consequently, access timings between the CPU 1 and the peripheral equipment need not be considered, which facilitates development of an application program.

FIG. 6 illustrates writing processing of data from the CPU 1 into the device 8. Referring to FIG. 6, the address (Address) ((c) of FIG. 6) allocated to the device 8 is first outputted from the CPU 1 by way of the main bus 9. The address is latched by the address buffer 21 and inputted to the main bus address decoder 17.

The address latched by the address buffer 21 is outputted as a signal SAddress ((h) of FIG. 6) to the sub bus 10 and outputted also to the sub bus address decoder 19.

The address from the CPU 1 is decoded by the main bus address decoder 17 and the sub bus address decoder 19, and results of such decoding are compared with the address decode table stored in the address table storage section 18.

Since the address allocated to the device 8 is held outputted from the CPU 1 as described above, it is detected by the sub bus address decoder 19 that the peripheral equipment the CPU 1 tries to access is the device 8, and a chip select signal (ChipSelect) ((f) of FIG. 6) is outputted from the sub bus address decoder 19 to the device 8 by way of the sub bus 10.

The result of decoding of the sub bus address decoder 19 is stored into the status buffer 20 and then outputted from the status buffer 20 to the controller 16. Consequently, the controller 16 recognizes that the object for accessing of the CPU 1 is the device 8.

Further, from the CPU 1, a write signal (Write) ((b) of FIG. 6) is supplied to the controller 16 by way of the main bus 9 and data (Data) are supplied to and latched by the data buffer 11.

After the data (Data) from the CPU 1 are latched by the data buffer 11, the controller 16 supplies a DataOk signal ((e) of FIG. 6) indicating that writing of the data (Data) into the device 8 has been completed (although such writing has not been completed as yet) to the CPU 1 by way of the main bus 9.

Upon reception of the DataOk signal, the CPU 1 recognizes that writing of the data (Data) has been completed, and stops outputting of the write signal (Write), the address (Address) and the data (Data), whereafter it executes next processing.

Meanwhile, upon reception of the write signal (Write) from the CPU 1, the controller 16 outputs a write signal (SWrite) ((g) of FIG. 6) to the sub bus 10 and outputs a control signal to the data buffer 11 to output the latched data as a signal SData ((i) of FIG. 6) to the sub bus 10.

Consequently, data (Sdata) are outputted from the data buffer 11 to the sub bus 10.

Here, the device 8 has a write delay time of 3 clocks as seen from the timing table of FIG. 3. In particular, the device 8 requires the time for three clocks before data are fetched from the sub bus 10 after a chip select signal and a write signal (SWrite) are supplied thereto.

Further, the device 8 has a hold time of one clock. In particular, when it is tried to perform writing of data into the device 8 (in order to assure writing of data into the device 8), the data (SData) and the address (SAddress) must necessarily be continued to be supplied to the sub bus 10 before the time at least for one clock elapses after supplying of the write signal (SWrite) is stopped.

Thus, the controller 16 first resets, after it outputs a write signal (SWrite) ((g) of FIG. 6) to the sub bus 10, the counter 15 and then causes the counter 15 to start counting beginning with 0 at the timing of a system clock ((a) of FIG. 6).

Further, the controller 16 refers to the write delay time of the device 8 described in the timing table (FIG. 3) of the timing table storage section 13 and places a waiting time until after the count value of the counter

15 becomes equal to the write delay time of the device 8.

Accordingly, in this instance, after the write signal (SWrite) is outputted, a waiting time for three clocks is placed.

When the time for three clocks elapses after the write signal (SWrite) is outputted to the sub bus 10, outputting of the write signal (SWrite) and the chip select signal from the controller 16 is stopped.

After the controller 16 stops outputting of the write signal (SWrite) ((g) of FIG. 6), it resets the counter 15 and then causes the counter 15 to start counting beginning with 0 at the timing of a system clock ((a) of FIG. 6).

Thereafter, the controller 16 refers to the hold time of the device 8 described in the timing table (FIG. 3) of the timing table storage section 13 and places a waiting time until after the count value of the counter 15 becomes equal to the hold time of the device 8.

Accordingly, in this instance, a waiting time for one clock is placed after outputting of the write signal (SWrite) is stopped.

When the time for one clock elapses after outputting of the write signal (SWrite) is stopped (at a timing (the point of time denoted at P₂ in FIG. 6) of a first rising edge of the system clock signal after lapse of the time for more than one clock), outputting of the data (Sdata) or the address (SAddress) from the data buffer 11 or the address buffer 21 is stopped, thereby completing the writing processing of data into the device 8.

The accessing timings to the device 8 which has a hold time are controlled in such a manner as described above so that writing of data into the device 8 is assured (data are written accurately into the device 8).

Further, writing processing of data into the device 8 is transferred from the CPU 1 to the gateway 4 so that the writing processing is thereafter executed by the gateway 4. Accordingly, the CPU 1 can immediately execute any other processing as described above, and consequently, the processing speed of the entire apparatus can be enhanced.

Subsequently, when, for example, writing of data into the memory 6 is successively performed twice (when accessing to the memory 6 is successively performed twice), similar processing to that in the writing processing of data into the device 8 described above is first performed for the first time.

In particular, the gateway 4 executes timing control taking the write delay time (FIG. 3) of the memory 6 into consideration (the hold time (FIG. 3) of the memory 6 is ignored since it is equal to 0).

Here, the memory 6 has a recovery time of 10 clocks as seen from the timing table of FIG. 3. In particular, when it is tried to successively access the memory 6 twice, second time accessing is not assured before the time for 10 clocks elapses after first

time accessing comes to an end.

Thus, in the gateway 4, after second time accessing to the memory 6 is started after completion of first time accessing to the memory 6 and a result of decoding of the address allocated to the peripheral equipment to which the sub bus address decoder 19 has outputted a chip select signal is supplied to the status buffer 20, the result of the decoding is compared with a stored value currently stored in the status buffer 20.

Here, when the first time writing processing of data into the memory 6 comes to an end, the last result of decoding of the sub bus address decoder 19, that is, the fact that the peripheral equipment which has been accessed last is the memory 6, is stored in the status buffer 20.

Accordingly, in this instance, it is determined that the result of decoding just outputted from the sub bus address decoder 19 is equal to the stored value stored in the status buffer 20.

Consequently, the controller 16 executes recovery processing.

In particular, the controller 16 first resets the counter 15 and causes the counter 15 to start counting beginning with 0 at the timing of a system clock.

Simultaneously, the controller 16 refers to the recovery time of the memory 6 described in the timing table (FIG. 3) of the timing table storage section 13, and if the recovery time is longer than 0, the controller 16 places a waiting time until the count value of the counter 15 becomes equal to the recovery time of the memory 6.

Accordingly, in this instance, after the first time accessing to the memory 6 comes to an end, a waiting time (interval) for 10 clocks is placed, and thereafter, second time writing of data into the memory 6 is performed.

The accessing timing to the memory 6 which has a recovery time is controlled in such a manner as described above, and even if accessing to the memory 6 occurs successively, the operation in such accessing is assured.

Meanwhile, data outputted as write data for the second time from the CPU 1 to the memory 6 after completion of the first time accessing to the memory 6 by the gateway 4 are latched immediately by the data buffer 11 of the gateway 4.

Then, a signal DataOk is outputted from the controller 16 to the CPU 1.

Consequently, the CPU 1 recognizes that writing of the data into the memory 6 has been completed (although actually the data have been merely latched by the data buffer 11 and writing of the data into the memory 6 is not completed as yet), and the main bus 9 is released. Accordingly, the CPU 1 can execute another processing immediately after completion of the first time accessing to the memory 6 by the gateway 4, and consequently, the processing speed of the entire apparatus can be enhanced.

It is to be noted that the timing table (FIG. 3) stored in the timing table storage section 13 can be rewritten by the CPU 1 executing a predetermined program. Accordingly, even if the specifications of, for example, any of the ROM 5, the backup memory 6, and the devices 7 and 8 are varied or a new peripheral equipment is added, only it is necessary to re-write the timing table, and such a situation that, for example, the compatibility of application software which has been used till now is lost to disable use of the application software is eliminated.

Subsequently, control of the bus width and the addressing type will be described with reference to the flow charts of FIGS. 7 and 8. It is to be noted that, in FIGS. 7 and 8, the signals Read, DataOK, ChipSelect, SRead and SWrite are indicated in the active-low logic. Further, it is assumed that each block of the apparatus operates in synchronism with the timing of a rising edge of the system clock ((a) of FIG. 7 and (a) of FIG. 8).

For example, when the CPU 1 tries to read out data of 32 bits from the ROM 5 of 8 bits, an address (Address) ((c) of FIG. 7) of the data to be read out from the ROM 5 is outputted from the CPU 1 by way of the main bus 9. The address is latched by the address buffer 21 and inputted to the main bus address decoder 17.

The address latched by the address buffer 21 is outputted as a signal SAddress ((h) of FIG. 7) to the sub bus 10 and outputted to the sub bus address decoder 19.

The address from the CPU 1 is decoded by the main bus address decoder 17 and the sub bus address decoder 19, and a result of the decoding is compared with the address decode table stored in the address table storage section 18.

Since the address of the ROM 5 is outputted from the CPU 1 as described above, it is detected by the sub bus address decoder 19 that the peripheral equipment the CPU 1 tries to access is the ROM 5, and a chip select signal (ChipSelect) ((f) of FIG. 7) is outputted from the sub bus address decoder 19 to the ROM 5 by way of the sub bus 10.

The result of decoding of the sub bus address decoder 19 is stored into the status buffer 20 and then outputted from the status buffer 20 to the controller 16. Consequently, it is recognized by the controller 16 that the object for accessing of the CPU 1 is the ROM 5.

Further, a read signal (Read) ((b) of FIG. 7) and an accessing type signal (AccessType) indicating that the length of data to be read out is 32 bits are supplied from the CPU 1 to the controller 16 by way of the main bus 9.

Upon reception of the read signal (Read) from the CPU 1, the controller 16 outputs a read signal (SRead) ((g) of FIG. 7) to the sub bus 10.

Consequently, data of 8 bits (Sdata) ((i) of FIG.

7) are outputted from the address (SAddress) of the ROM 5 to the lower 8 bits of the sub bus 10 of 16 bits.

Here, the ROM 5 has a bus width of 8 bits and a variable addressing type as seen from the bus width table of FIG. 4. In other words, in order to read out data of 32 bits indicated by an accessing type signal (AccessType) from the ROM 5, the processing of reading out data in units of 8 bits as the bus width unit must necessarily be performed four times incrementing (or decrementing) the address.

Therefore, the controller 16 executes the following control in accordance with the accessing type signal (AccessType) received from the CPU 1 and the bus width and the addressing type of the ROM 5 described in the bus width table (FIG. 4) of the bus width table storage section 14.

In particular, where four data obtained by dividing data of 32 bits by 8 bits are represented, beginning with the uppermost 8 bits, by d_4 , d_3 , d_2 and d_1 , if it is assumed that the four 8-bit data d_4 , d_3 , d_2 and d_1 are written at addresses of SAddress+3, SAddress+2, SAddress+1 and SAddress of the ROM 5, then the controller 16 first causes 8-bit data outputted from the address (SAddress) of the ROM 5 to the sub bus 10 as described above to be latched at the lower 8 bits of the data buffer 11 of 32 bits by way of the multiplexer 12d.

Thereafter, the controller 16 causes the address (SAddress (= Address)) latched in the address buffer 21 to be incremented by one and outputs the resulted new address (SAddress+1) to the ROM 5 by way of the sub bus 10.

Consequently, data of 8 bits are outputted from the address (SAddress+1) of the ROM 5 to the sub bus 10. The 8-bit data are latched as data of next 8 bits to the lower 8 bits by the data buffer 11 by way of the multiplexer 12c.

Thereafter, data of 8 bits are read out successively from the addresses (SAddress+2 and SAddress+3) of the ROM 5 and latched successively by the data buffer 11 in a similar manner as described above. It is to be noted that, in this instance, the controller 16 turns the read signal (SRead) to the ROM 5 on or off as seen from (g) of FIG. 7 in response to the timing at which the address stored in the address buffer 21 is incremented.

After the 8-bit data read out from the addresses (SAddress, SAddress+1, SAddress+2 and SAddress+3) of the ROM 5 are latched by the data buffer 11 in such a manner as described above to form data of 32 bits, that is, after four data of 8 bits are packed into data of 32 bits, the controller 16 outputs a signal DataOK ((e) of FIG. 7) to the CPU 1 by way of the main bus 9 and causes the data of 32 bits ((d) of FIG. 7) latched in the data buffer 11 to be outputted to the main bus 9.

Upon reception of the signal DataOK, the CPU 1 fetches the data of 32 bits on the main bus 9, thereby

completing reading of the data of 32 bits from the ROM 5.

It is to be noted that the bus width table (FIG. 4) stored in the bus width table storage section 14 can be re-written by the CPU 1 executing a predetermined program. Accordingly, if, for example, the ROM 5 is changed from an 8-bit ROM to a 16-bit ROM, it is only necessary to change the bus width of the ROM 5 of the bus width table (FIG. 4) from 8 bits to 16 bits.

In this instance, two 16-bit data are read out from the ROM 5, and one of the two data, for example, the data of 16 bits of the lower address, are latched at the lower 16 bits of the data buffer 11 by way of the multiplexers 12c and 12d and the other of the two data, for example, the data of 16 bits of the upper address, are latched at the upper 16 bits of the data buffer 11 by way of the multiplexers 12a and 12b so that the two 16-bit data are packed into 32-bit data.

Subsequently, when the CPU 1 tries to write data of 32 bits into the device 7, an address (Address) ((c) of FIG. 8) of the device 7 into which data are to be written is outputted from the CPU 1 by way of the main bus 9. The address is latched by the address buffer 21 and inputted to the main bus address decoder 17.

The address latched by the address buffer 21 is outputted as a signal SAddress ((h) of FIG. 8) to the sub bus 10, and is outputted to the sub bus address decoder 19.

The address from the CPU 1 is decoded by the main bus address decoder 17 and the sub bus address decoder 19, and a result of the decoding is compared with the address decode table stored in the address table storage section 18.

Since the address of the device 7 is outputted from the CPU 1 as described above, it is detected by the sub bus address decoder 19 that the peripheral equipment the CPU 1 tries to access is the device 7, and a chip select signal (ChipSelect) ((f) of FIG. 8) is outputted from the sub bus address decoder 19 to the device 7 by way of the sub bus 10.

The result of decoding of the sub bus address decoder 19 is stored into the status buffer 20 and outputted from the status buffer 20 to the controller 16. Consequently, it is recognized by the controller 16 that the object for accessing of the CPU 1 is the device 7.

Further, a write signal (Write) and an accessing type signal (AccessType) indicating that the length of data to be written is 32 bits are supplied from the CPU 1 to the controller 16 by way of the main bus 9, and data (Data) ((d) of FIG. 8) to be written into the device 7 are outputted from the CPU 1 to the main bus 9.

Upon reception of the write signal (Write) from the CPU 1, the controller 16 causes the data buffer 11 to latch the 32-bit data on the main bus 9 and outputs a write signal (SWrite) ((g) of FIG. 8) to the sub bus 10.

Further, the controller 16 outputs a signal Data-

OK to the CPU 1. Consequently, the CPU 1 recognizes that writing of data into the device 7 has been completed (although such writing has not actually been completed as yet), and the main bus 9 is released. Accordingly, since the CPU 1 thereafter can execute any other processing immediately, the processing speed of the entire apparatus can be enhanced.

Here, the device 7 has a bus width of 8 bits and a fixed addressing type as seen from the bus width table of FIG. 4. In particular, in order to write data of 32 bits indicated by the accessing type signal (AccessType) into the device 7, it is necessary to divide the 32-bit data equally into four data of 8 bits as a bus width unit of the device 7 and write the four 8-bit data fixing the address.

Therefore, the controller 16 executes the following control in accordance with the accessing type signal (AccessType) received from the CPU 1 and a bus width and an addressing type of the device 7 described in the bus width table (FIG. 4) of the bus width table storage section 14.

In particular, the controller 16 causes data of 32 bits latched in the data buffer 11 to be read out into the multiplexers 12a to 12d of an 8-bit width to unpack the data into four 8-bit data.

The controller 16 then causes the data of 8 bits on the LSB (least significant bit) side of the 32-bit data read out by the multiplexer 12d to be outputted to the lower 8 bits of the sub bus 10. Consequently, the data of 8 bits are written into the address (SAddress) of the device 7.

Further, the controller 16 causes the address buffer 21 to output the data of next upper 8 bits to the 8 bits on the LSB side of the 32-bit data, which have been read out by the multiplexer 12c, while leaving the address buffer 21 to hold the stored address (SAddress), to the lower 8 bits of the sub bus 10. Consequently, the data of 8 bits are written into the address (SAddress) of the device 7.

Thereafter, the remaining two data of 8 bits read out from the data buffer 11 by the multiplexers 12b and 12a are successively written into the address (SAddress) of the device 7 in a similar manner as described above. It is to be noted that, in this instance, the controller 16 causes the multiplexers 12a to 12d to successively turn on and off the write signal (SWrite) to the device 7 as seen from (g) of FIG. 8 in accordance with the timing at which data are read out from the data buffer 11.

The device 7 has a buffer of, for example, of the FIFO type, and the four data of 8 bits written into the address (SAddress) are successively stacked (loaded) into the buffer and are thereafter processed by predetermined processing by the device 7.

It is to be noted that, when, for example, the device 7 is changed from the device having a bus width of 8 bits to another device having another bus width of 16 bits, it is only necessary to change the bus width

of the device 7 in the bus width table (FIG. 4) from 8 bits to 16 bits in a similar manner as described hereinabove.

In this instance, the data of lower 16 bits of the 32-bit data latched in the data buffer 11 are read out by the multiplexers 12c and 12d and the data of upper 16 bits are read out by the multiplexers 12a and 12b to unpack the 32-bit data into two 16-bit data.

Accordingly, even if the bus width or the addressing type of the peripheral equipment is changed or a new peripheral equipment is added, it is only necessary to re-write the bus width table, and such a situation that, for example, the compatibility of application software which has been used till now is lost to disable use of the application software is eliminated.

While the control of the timings and the control of the bus width and the addressing type have been described separately from each other in order to facilitate understanding, those controls are executed parallelly or simultaneously as illustrated in a flow chart of FIG. 9 by the gateway 4 in accordance with the timing table (FIG. 3) and the bus width table (FIG. 4).

In particular, the gateway 4 first waits that an address is outputted together with a write signal or a read signal from the CPU 1 by way of the main bus 9. Then, after an address is outputted together with a write signal or a read signal from the CPU 1, the control sequence advances to step S2, at which the address from the CPU 1 is outputted to the peripheral equipment and decoding of the address is performed. Then, the gateway 4 outputs a chip select signal to one of the peripheral equipment indicated by a result of the decoding.

The control sequence then advances to step S3, at which it is determined from the result of decoding of the address from the CPU 1 whether or not the peripheral equipment the CPU 1 tries to access is connected to the sub bus 10.

When it is determined at step S3 that the peripheral equipment the CPU 1 tries to access is not connected to the sub bus 10, that is, when the peripheral equipment the CPU 1 tries to access is connected to the main bus 9, the recovery processing described above need not be executed, and consequently, the control sequence advances to step S4, at which the status buffer 20 is cleared, whereafter the control sequence advances to step S5.

At step S5, accessing of the CPU 1 to the peripheral equipment connected to the main bus 9 is performed, and after such accessing comes to an end, the control sequence returns to step S1 to repeat the processes beginning with step S1.

On the other hand, when it is determined at step S3 that the peripheral equipment the CPU 1 tries to access is connected to the sub bus 10, the control sequence successively advances to steps S6 and S7, at which the timing table and the bus width table are

read out from the timing table storage section 13 and the bus width table storage section 14, respectively.

Thereafter, the control sequence advances to step S8, at which it is determined whether or not the accessing type of the CPU 1 and the bus width of the peripheral equipment the CPU 1 tries to access are equal to each other. When it is determined at step S8 that the accessing type of the CPU 1 and the bus width of the peripheral equipment the CPU 1 tries to access are equal to each other, the control sequence advances to step S10, at which a variable N is set to 1, whereafter the control sequence advances to step S11.

On the other hand, when it is determined at step S8 that the accessing type of the CPU 1 and the bus width of the peripheral equipment the CPU 1 tries to access are not equal to each other, the control sequence advances to step S9, at which the variable N is set to the number of times by which packing/unpacking should be performed, whereafter the control sequence advances to step S11.

At step S11, it is determined whether the signal outputted from the CPU 1 at step S1 is a write signal or a read signal.

If it is determined at step S11 that the signal outputted from the CPU 1 at step S1 is a read signal, the control sequence advances to step S13, at which reading processing of data from the peripheral equipment is performed.

In particular, at step S13, recovery processing is first executed at step S21 illustrated in FIG. 10.

Here, the recovery processing at step S13 proceeds in such a manner as illustrated in a flow chart of FIG. 11.

In particular, referring to FIG. 11, the address buffer 21 is first referred to at step S31 to determine whether or not the peripheral equipment the CPU 1 now tries to access is the peripheral equipment which has been accessed last by the CPU 1.

If it is determined at step S31 that the peripheral equipment the CPU 1 tries to access is not the peripheral equipment which has been accessed last by the CPU 1, the control sequence advances to step S32, at which the peripheral equipment the CPU 1 tries to access now is stored into the status buffer 20, thereby completing the processing.

On the other hand, if it is determined at step S31 that the peripheral equipment the CPU 1 tries to access now is the peripheral equipment which has been accessed last by the CPU 1, then the control sequence advances to step S33, at which the timing table (FIG. 3) is referred to to determine whether or not the peripheral equipment the CPU 1 tries to access now has a recovery time.

If it is determined at step S33 that the peripheral equipment the CPU 1 tries to access now does not have a recovery time, the processing is completed immediately.

On the other hand if it is determined at step S33 that the peripheral equipment the CPU 1 tries to access now has a recovery time, the control sequence advances to step S34, at which a waiting time for the recovery time is placed, thereby completing the processing.

After the recovery processing at steps S31 to S34 is completed in such a manner as described above, that is, if the processing at step S21 of FIG. 10 is completed, then the control sequence advances to step S22, at which a read signal (SRead) is outputted by way of the sub bus 10 to the peripheral equipment from which the CPU 1 tries to read data, whereafter the control sequence advances to step S23.

At step 23, a waiting time for the read delay time of the peripheral equipment from which the CPU 1 tries to read data, which is described in the timing table of the timing table storage section 13, is placed, whereafter the control sequence advances to step S24, at which data are read out from the peripheral equipment. The data thus read out are latched from the lower bit side thereof into the data buffer 11, and outputting of the read signal (SRead) is stopped.

The control sequence then advances to step S25, at which it is determined whether or not the peripheral equipment from which the data have been read out has a floating time. If it is determined at step S25 that the peripheral equipment from which the data have been read out has a floating time, then the control sequence advances to step S26, at which a waiting time for the floating time is placed, whereafter the control sequence advances to step S27.

On the other hand, if it is determined at step S25 that the peripheral equipment from which the data have been read out does not have a floating time, the control sequence advances, skipping the step S26, to step S27, at which the variable N is decremented by one.

The control sequence then advances to step S28, at which it is determined whether or not the variable N is equal to 0. If it is determined at step S28 that the variable N is not equal to 0, the control sequence advances to step S29, at which outputting processing of a next address for further reading out data from the peripheral equipment is executed.

In particular, at step S29, the bus width table (FIG. 4) read out from the bus width table storage section 14 at step S7 in FIG. 9 is referred to, first at step S41 illustrated in FIG. 12, to determine whether or not the addressing type of the peripheral equipment from which the data have been read out is the fixed type.

If it is determined at step S41 that the addressing type of the peripheral equipment from which the data have been read out is the fixed type, that is, when the address stored in the address buffer 21 need not be incremented or decremented in order to further read out data from the peripheral equipment, the process-

ing is completed skipping the step S42.

On the other hand, if it is determined at step S41 that the addressing type of the peripheral equipment from which the data have been read out is not the fixed type but the variable type, the control sequence advances to step S42, at which the address stored in the address buffer 21 is incremented by one, thereby completing the processing.

After the outputting processing for a next address is completed in such a manner as described above, that is, after processing at step S29 of FIG. 10 has been completed, the control sequence returns to step S21 until it is determined at step S28 that the variable N is equal to 0, the processing at step S21 to S29 are repeated.

Namely, at steps S21 to 29, data of the prescribed bus width are read out successively from the peripheral equipment and successively latched from the lower bit side thereof by the data buffer 11 to pack the data. The processing just described is repeated by the number of times given by (accessing type of the CPU 1)/(bus width of the peripheral equipment).

On the other hand, when it is determined at step S28 that the variable N is equal to 0, that is, when the data length of the data successively latched from the lower bit side thereof by the data buffer 11 becomes equal to the accessing type of the CPU 1 as a result of the processing at steps S21 to S29 described above, the control sequence advances to step S30, at which the data latched in the data buffer 11 are supplied to the CPU 1 by way of the main bus 9, thereby completing the processing.

After the reading processing of data from the peripheral equipment is completed in such a manner as described above, that is, after the processing at step S13 of FIG. 9 is completed, the control sequence advances to step S14.

On the other hand, if it is determined at step S11 of FIG. 9 that the signal outputted from the CPU 1 at step S1 is a write signal, the control sequence advances to step S12, at which writing processing of data into the peripheral equipment is executed.

In particular, at step S12, the data outputted from the CPU 1 by way of the main bus 9 are first latched by the data buffer 11. Then at step S51 illustrated in FIG. 13, a signal DataOK is outputted to the CPU 1, whereafter the control sequence advances to step S52.

Consequently, the CPU 1 recognizes that writing of data into the peripheral equipment has been completed (although such writing has not actually been completed as yet) as described hereinabove.

Then at step S52, recovery processing similar to that at step S21 of FIG. 10 (steps S31 to S34 of FIG. 11) described above is executed, whereafter the control sequence advances to step S53, at which the data from the CPU 1 latched in the data buffer 11 are read out from the lower bit side thereof by way of the mul-

tiplexers 12a to 12d in accordance with the bus width (8 bits or 16 bits in the present embodiment) of the peripheral equipment, into which the data should be written. The data thus read out are outputted as signal SData to the sub bus 10 while a write signal (SWrite) is outputted to the sub bus 10.

The control sequence then advances to step S54, at which the write delay time of the peripheral equipment, into which it is tried to write data, which is described in the timing table read out from the timing table storage section 13 at step S6 of FIG. 9, is referred to to place a waiting time corresponding to the write delay time.

Consequently, the data read out from the data buffer 11 are written into the peripheral equipment in accordance with the bus width of the peripheral equipment.

Thereafter, outputting of the write signal (SWrite) is stopped at step S55, and then it is determined at step S56 whether or not the peripheral equipment into which the data have been written has a hold time. If it is determined at step S56 that the peripheral equipment into which the data have been written has a hold time, the control sequence advances to step S57, at which a waiting time for the hold time is placed, whereafter the control sequence advances to step S58.

On the other hand, if it is determined at step S56 that the peripheral equipment into which the data have been written does not have a hold time, the control sequence advances, skipping the step S57, to step S58, at which the variable N is decremented by one.

The control sequence then advances to step S59, at which it is determined whether or not the variable N is equal to 0. If it is determined at step S59 that the variable N is not equal to 0, the control sequence advances to step S60, at which outputting processing of a next address and next data for further writing data into the peripheral equipment is executed.

In particular, at step S60, the bus width table (FIG. 4) read out from the bus width table storage section 14 at step S7 of FIG. 9 is first referred to at step S71 illustrated in FIG. 14 to determine whether or not the bus width of the peripheral equipment into which the data have been written is 8 bits.

If it is determined at step S71 that the bus width of the peripheral equipment into which the data have been written is not 8 bits, that is, when the bus width is 16 bits (in the present embodiment, the bus width of the peripheral equipment connected to the sub bus 10 is either 8 bits or 16 bits), the control sequence advances to step S72, at which the upper 16 bits of the 32-bit data latched in the data buffer 11 are outputted to the multiplexers 12a and 12b, whereafter the control sequence advances to step S74.

On the other hand, if it is determined at step S71

that the bus width of the peripheral equipment into which the data have been written is 8 bits, the control sequence advances to step S73, at which upper 8 bits next to the 8 bits outputted last from among the 32-bit data latched in the data buffer 11 are outputted to the multiplexer 12c (or 12b or 12a), whereafter the control sequence advances to step S74.

At step S74, the bus width table (FIG. 4) is referred to again to determine whether or not the addressing type of the peripheral equipment into which the data have been written is the fixed type.

If it is determined at step S74 that the addressing type of the peripheral equipment into which the data have been written is the fixed type, that is, when the address stored in the address buffer 21 need not be incremented or decremented in order to further write data into the peripheral equipment, the processing is completed skipping the step S75.

On the other hand, if it is determined at step S74 that the addressing type of the peripheral equipment into which the data have been written is not the fixed type but the variable type, the control sequence advances to step S75, at which the address stored in the address buffer 21 is incremented by one, thereby completing the processing.

After the outputting processing of a next address and next data is completed in such a manner as described above, that is, after the processing at step S60 of FIG. 13 is completed, the control sequence returns to step S51 in order to repeat the processing at steps S51 to S60 until after it is determined at step S59 that the variable N is equal to 0.

In particular, data are successively read out from the lower bit side thereof from the data buffer 11, in which the data from the CPU 1 are stored, in accordance with the bus width of the peripheral equipment to unpack and write the data into the peripheral equipment. The processing just described is repeated by the number of times given by (accessing type of the CPU 1)/(bus width of the peripheral equipment).

On the other hand, if it is determined at step S59 that the variable N is equal to 0, that is, when the data stored in the data buffer 11 have been successively read out from the lower bit side thereof and all written into the peripheral equipment as a result of the processing at steps S51 to S60, the control sequence advances to step S61, at which outputting of the data (SData) to the peripheral equipment is stopped, thereby completing the processing.

After the writing processing of data into the peripheral equipment is completed in such a manner as described above, that is, after the processing at step S12 of FIG. 9 is completed, the control sequence successively advances to steps S14 and S15, at which outputting of the chip select signal and the address (SAddress), which has been outputted to the peripheral apparatus, is stopped.

Thereafter, the control sequence returns to step

S1 to repeat the processing beginning with step S1.

Since the control of timings and the control of the bus width and the addressing type are performed parallelly (simultaneously) in such a manner as described above by the gateway 4, the processing speed of the entire apparatus can be enhanced and an application program which is reduced in dependency upon hardware can be provided.

Having now fully described the invention, it will be apparent to one of ordinary skill in the art that many changes and modifications can be made thereto without departing from the spirit and scope of the invention as set forth herein.

Claims

1. A bus control apparatus for interconnecting a plurality of bus lines, comprising:
 - a main bus to which a central processing unit is connected;
 - a sub bus to which a peripheral equipment is connected;
 - storage means for storing an operation timing of said peripheral equipment; and
 - control means for controlling an access timing between said central processing unit and said peripheral equipment in accordance with the operation timing of said peripheral equipment stored in said storage means.
2. A bus control apparatus for interconnecting a plurality of bus lines, comprising:
 - a main bus to which a central processing unit is connected;
 - a sub bus to which a peripheral equipment is connected;
 - storage means for storing a bus width and an addressing type of said peripheral equipment;
 - data latch means for latching data outputted from said central processing unit or said peripheral equipment;
 - address latch means for latching an address outputted from said central processing unit to said peripheral equipment; and
 - control means for controlling packing/unpacking of data latched in said data latch means in accordance with the bus width of said peripheral equipment stored in said storage means and controlling the address latched in said address latch means in accordance with the addressing type of said peripheral equipment stored in said storage means.
3. A bus control apparatus according to claim 1 or 2, wherein the operation timing of said peripheral equipment stored in said storage means is rewritable.

4. A bus control apparatus according to claim 1, 2 or 3, wherein said storage means stores at least a hold time or a recovery time of said peripheral equipment. 5
5. A bus control apparatus according to any one of claims 1 to 4, wherein said main bus has a bus width greater than the bus width of said sub bus. 10
6. A bus control apparatus according to any one of the preceding claims, wherein the bus width of said main bus is equal to an integral number of times the bus width of said sub bus. 15
7. A bus control apparatus according to claim 6, wherein the bus width and the addressing type of said peripheral equipment stored in said storage means are re-writable. 20
8. A bus control apparatus according to claim 7, wherein said storage means stores at least a hold time or a recovery type of said peripheral equipment. 25
9. A bus control apparatus according to claim 8, wherein the bus width of said main bus is greater than the bus width of said sub bus. 30
10. A bus control apparatus according to claim 9, wherein the bus width of said main bus is equal to an integral number of times the bus width of said sub bus. 35
